Are periodontal diseases risk factors for certain systemic disorders—what matters to medical practitioners?

牙周病是否某些系统性疾病的风险因素——与全科及专科医生有何关系?

Objective. To review recent data on the nature and pathobiology of periodontal infections and to elaborate how periodontal infections might increase susceptibility to some important systemic diseases and conditions.

Study selection. Literature and data on periodontal diseases and their links to systemic diseases.

Data extraction. Review of relevant information and data.

Data synthesis. Periodontal diseases, including gingivitis and periodontitis, are among the most common infections of humans. They are induced by bacteria and bacterial products of dental plaque and are characterised by inflammatory destruction of tooth-supporting connective tissues and alveolar bone. A growing body of scientific evidence has shown that severe periodontitis may enhance susceptibility to certain important systemic diseases and conditions, for example, cardiovascular disease, diabetes mellitus, adverse pregnancy outcomes, and pulmonary infections. The clinical implications of the emerging specialty of periodontal medicine for dental and medical practitioners are postulated.

Conclusions. Periodontal diseases may be risk factors for cardiovascular disease, diabetes mellitus, adverse pregnancy outcomes, and pulmonary infections. Dental and medical practitioners should be aware of the clinical implications of these inter-relationships and treat affected patients in collaboration for better oral and general health.
remain contained in the marginal gingival tissues or it may develop into periodontitis with destruction of tooth-supporting periodontal tissues and alveolar bone—this is termed periodontal attachment loss and alveolar bone loss. With progression of destruction of the tooth-supporting tissues, pockets form between the teeth and the surrounding detached periodontal tissues. Teeth may become loose and may eventually be lost. Although periodontal diseases are prevalent, advanced loss of periodontal tooth-supporting tissues only affects a limited portion of the population in both developed and developing countries. Most adults in Hong Kong who do not clean their teeth effectively have varying degrees of periodontal diseases and approximately 16% may show some evidence of advanced loss of periodontal attachment.

### Nature of periodontal diseases

It is estimated that $10^{14}$ normal or commensal microbes reside on the surfaces of teeth, prosthetic implants, dentures, dental restorations, and the mucosal epithelia lining the oral cavity, respiratory tract, gastrointestinal tract, and urinary tract. The oral cavity contains almost half the commensal bacteria in the human body—approximately six billion microbes representing 300 to 500 species. In certain conditions, some of these micro-organisms may become opportunistic species that contribute to local and/or systemic infections. It is known that the oral microbial ecosystem is highly dynamic and the oral cavity faces a constant challenge of opportunistic infections and various oral complications of systemic diseases and disorders.

In some ways, periodontal diseases are among the most unusual human infections. The major reason for this uniqueness is the unusual anatomic feature that the tooth passes through the integument, so that part of it is exposed to the external environment while part is solidly rooted in the connective tissues. In contrast to the outer surface of most parts of the body, the outer layers of the tooth do not shed and thus provide a relative stable surface for microbial colonisation. This facilitates micro-organisms maintaining continuous immediate proximity to the periodontal tissues. Furthermore, the tooth surface and the attached micro-organisms are immersed in an aqueous environment, where any bacterial infection is less able to be controlled by the potent mechanisms of host defences and antimicrobial therapy.

Periodontal diseases are understood to be initiated and perpetuated by a group of predominantly gram-negative and anaerobic bacteria from bacterial plaque, a sticky, colourless film that constantly forms on tooth surfaces, known as a plaque ‘biofilm’. This constantly reforming bacterial biofilm can be controlled by daily effective oral hygiene measures such as tooth brushing and the use of dental floss for cleaning between the teeth. If personal plaque control is ineffective and plaque build-up occurs, inflammation of the marginal gingival tissues usually ensues. Swelling of the gingival tissues is one clinical component of the inflammatory changes. This swelling of the marginal gingival tissues leads to the deepening of the gingival sulcus that is found between the tooth and the surrounding gingiva. This deepened gingival sulcus allows for the establishment of an anaerobic environment below the gingival margin (gum line) and the plaque that forms in this environment is termed subgingival plaque. The subgingival plaque biofilm is extraordinarily persistent and difficult to eliminate without the professional tooth cleaning by a dentist or dental hygienist. The amount of bacteria in the plaque biofilm increases with increasing severity of the disease, as more root surfaces are exposed to the environment that supports plaque biofilm growth and adhesion. Deepening of the subgingival environment allows for the establishment of a complex subgingival plaque with many potentially pathogenic micro-organisms. The important periodontal pathogens include *Actinobacillus actinomycetemcomitans*, *Bacteroides forsythus*, and *Porphyromonas gingivalis*. These and other bacteria and their toxins irritate the periodontal connective tissues and stimulate a chronic inflammatory and immune response. It is believed that periodontal pathogenesis is characterised by bacterial lipopolysaccharide (LPS) activation of a series of pro-inflammatory cytokines and inflammatory mediators from host cells, for example, macrophages, neutrophils, and fibroblasts. The severity of the ensuing periodontal tissue destruction is dependent upon dynamic interactions between the microbial challenge and the host immuno-inflammatory response, and these events are influenced by a series of risk factors, including systemic factors (diabetes, immunodeficiency diseases, stress, and osteoporosis), genetic variations, and behavioural and environmental factors (tobacco smoking).

### Periodontal diseases as infectious burdens to systemic health

In advanced stages of periodontitis, the gums markedly separate from the teeth. Continuing destruction of the periodontal attachment and deep periodontal pockets may develop with significant loss of tooth-supporting tissues and alveolar bone. Under these conditions, the thin, highly permeable, and frequently ulcerated pocket epithelium is the only barrier between the bacterial biofilms and the underlying connective tissues. The strands of the pocket epithelium are easily broached, allowing large doses of bacterial toxins and other products access to the tooth-supporting connective tissues and blood vessels. In a patient with moderate-to-advanced periodontitis and a relatively complete dentition, it has been estimated that the total area of pocket epithelium in direct contact with subgingival biofilms is surprisingly large, being approximately $72 \text{ cm}^2$—the size of the palm of the human hand. It is apparent that in the presence of uncontrolled advanced periodontitis, microbial-induced infection presents a substantial infectious burden for the entire body by releasing bacteria, bacterial toxins, and other inflammatory mediators into the bloodstream that then affect other parts of the body. This notion
represents a paradigm shift in thinking about the directionality of oral and systemic associations.12

Oral, especially periodontal, infections have been regarded as a source of focal infections for a long time. Miller14 originally published his ‘focal infection theory’ in 1891, indicating that “micro-organisms or their waste products obtain entrance of parts of the body adjacent to or remote from the mouth.” Three different mechanisms by which oral bacteria may contribute to non-oral diseases have been described15:

1) metastatic infection caused by translocation of bacteria;
2) metastatic injury related to microbial toxins; and
3) metastatic inflammation due to immune injury.

The focal infection concept has recently been given more attention by the dental and medical communities. This is largely due to improvements in methods of sampling, cultivation, and identification of bacteria that revealed the presence of micro-organisms well known to be oral colonisers in a variety of infected non-oral sites.16

In recent years, a growing body of scientific evidence has suggested an association between periodontal infections and certain systemic diseases or conditions. The biological basis and several potential mechanisms by which periodontal diseases might influence these conditions have been proposed (Fig). It is believed that the periodontal pocket and the adjacent inflamed periodontal tissues may serve as a renewing reservoir for the overflow of various bacterial products, for example, LPS and inflammatory mediators such as interleukin-1β (IL-1β), tumour necrosis factor–α (TNF-α), and prostaglandin E2 (PGE2) into the circulation, which may subsequently affect the vascular endothelium and other cells and tissues distant from the periodontal tissues.13 Moreover, periodontal diseases and some systemic diseases and conditions may share common risk factors (smoking, stress, and genetic factors) and aetiologic pathways.12 It is conceivable that periodontal infections might pose additional risks for susceptible people, contributing to serious diseases such as coronary heart disease and stroke17; increasing pregnant women’s risks of having a preterm, low-birth-weight baby18; and posing a threat to people whose health is compromised by uncontrolled diabetes19 or respiratory diseases.20 If these assumptions of relationships gleaned from association studies are subsequently substantiated by interventional clinical trials, then controlling periodontal diseases would be established as not just important for maintaining oral health and a functional dentition for a lifetime, but also in contributing to keeping the rest of the body healthy.

**Periodontal diseases and cardiovascular diseases**

Current research indicates that various clusters of interactive risk factors contribute to the onset of cardiovascular diseases (CVD).21 The risk factors for CVD such as hypertension, hypercholesterolaemia, and smoking do not account for all the variations in the incidence and severity of CVD and other, as yet unrecognised, risk factors for CVD may play a role. These risk factors may include some common chronic infections.22 Recent evidence for microbial infections (notably herpes virus and *Chlamydia pneumoniae*) as independent risk factors for CVD illustrates these concerns.23 Increasing evidence suggests that one of these infection factors might be oral (notably periodontal) infections.24 In recent years, extraordinary progress has been made in understanding the link between periodontal diseases and CVD, and the potential effect of periodontal infections on risk for atherosclerosis, ischaemic heart disease, and stroke.12,24 Clinical studies have found that people with periodontal diseases are almost twice as likely to suffer from coronary artery disease as those without periodontal diseases.12,17 People diagnosed with acute cerebrovascular ischaemia, particularly non-haemorrhagic
stroke, were found to be more likely to have a periodontal infection.\textsuperscript{25} Peripheral vascular disease and CVD may share atherosclerosis as a common pathway. A recent study showed that periodontal disease might be a significant independent risk factor for development of peripheral vascular disease.\textsuperscript{26}

The biological mechanisms for the observed association of periodontal infections with CVD and stroke are not fully understood and no causal relationship has yet been established.\textsuperscript{32} Infection is a well-established risk factor for atheroma formation and thromboembolic events, however. Three pathways linking oral infections to systemic effects have been proposed,\textsuperscript{15,27} as already mentioned. Periodontal diseases might affect heart disease through the mechanism of oral bacteria, bacterial toxins, and induced inflammatory mediators entering the blood stream and contributing to chronic, systemic vascular challenge, directly resulting in platelet aggregation, adhesion, and vasculitis, with the subsequent cholesterol deposition, thromboembolic events, and atheroma formation.\textsuperscript{12,13} Another possibility is that the inflammation caused by periodontal disease induces inflammatory cell infiltration into major vessels, vascular smooth muscle proliferation, vascular fatty degeneration, and increasing plaque build-up, which contribute to swelling and thickening of the arteries.\textsuperscript{17} These events may lead to atherosclerosis and atheroma formation, and result in obstruction of normal blood flow, restricting the amount of nutrients and oxygen required for the heart to function properly, and eventually increase the risk of heart attacks. In addition, CVD and periodontal diseases have a number of common characteristics and may share a similar causative pathway through a hyper-inflammatory phenotype, for example, increased release of inflammatory cytokines and relevant mediators.\textsuperscript{12}

Moreover, periodontal diseases may also exacerbate existing heart conditions. It is known that poor dental hygiene and periodontal or periapical infections may produce bacteraemias even in the absence of dental procedures.\textsuperscript{28} Bacteraemias may be intensified in patients with periodontitis,\textsuperscript{29} and may occur during activities of daily living such as routine tooth brushing or chewing. The incidence and magnitude of bacteraemias of oral origin are directly proportional to the degree of oral inflammation and infection.\textsuperscript{30,31} It has therefore been recommended that individuals who are at risk for developing infective endocarditis and are at risk for, or have, existing CVD are strongly encouraged to establish and maintain the best possible oral health through regular professional care and home plaque control procedures to reduce a potential source of bacterial seeding.\textsuperscript{28,29} For the same reasons given above for patients at risk of cardiac events, establishing and maintaining good oral health is also of great importance for dental patients with joint prosthesis. With respect to prophylaxis for endocarditis, patients at risk for infective endocarditis may require antibiotic cover prior to dental procedures likely to cause bacteraemias. In 1997, the American Heart Association updated its recommendations for dental management of patients with infective endocarditis induced by odontogenic bacteraemias.\textsuperscript{34} Several heart conditions require special precautions by the dentist and the cardiologist prior to dental treatment, particularly for patients with prosthetic heart valves, those with a previous history of endocarditis, and those with congenital or acquired heart defects (most congenital cardiac malformations, damaged heart valves, and hypertrophic cardiomyopathy).

**Periodontal disease and diabetes mellitus**

It has been known for years that patients with uncontrolled diabetes have a high risk for periodontal diseases.\textsuperscript{32} While, in recent years, at least one study has shown a two-way relationship between periodontal disease and diabetes mellitus.\textsuperscript{35} Increasing scientific evidence shows that acute infections may alter the endocrinologic-metabolic status of the host, thus leading to difficulty with glycaemic control. Periodontal infection may adversely influence glycaemic control in diabetes and decrease insulin-mediated glucose uptake by skeletal muscle, resulting in poor glycaemic control. Moreover, induced production of pro-inflammatory mediators in periodontal disease also mediates insulin resistance and reduces insulin action.\textsuperscript{39} It is conceivable that unresolved periodontal disease could also increase blood sugar, contribute to increased periods of time when the body functions with high blood sugar, and make it harder for patients to control their blood sugar, putting poorly controlled patients with diabetes at a higher risk of the complications of the condition.

It has been shown that periodontal treatment directed at elimination of pathogenic species and controlling inflammation may have a positive impact on glycaemic control by restoring insulin sensitivity in poorly controlled patients with diabetes, possibly by suppressing glycosylation of proteins, formation of advanced glycation end-products, and activities of matrix metalloproteinases and other inflammatory mediators.\textsuperscript{39,33} Recent studies have shown that effective control of periodontal infection in patients with diabetes may reduce the level of advanced glycation end-products in the serum.\textsuperscript{34,35} In this regard, prevention of periodontal diseases and control of established periodontal diseases should be considered an integral part of diabetes control.\textsuperscript{36}

**Periodontal disease and adverse pregnancy outcomes**

Low birth weight, defined as birth weight less than 2500 g, continues to be a significant public health issue in both developed and developing countries. This obstetric complication is usually a direct result of preterm labour, in which case it is referred to as preterm delivery of low-birth-weight infants.\textsuperscript{37} It is known that various risk factors, such as older (greater than 34 years) and younger (less than 17 years) maternal age, inadequate prenatal care, smoking, drug and alcohol abuse, hypertension, genitourinary tract infection, diabetes mellitus, and multiple pregnancies contribute to
Periodontal diseases and systemic disorders

adverse pregnancy outcomes. However, the recognised risk factors alone do not wholly account for the high prevalence of preterm low-birth-weight infants. An important factor contributing to this problem is the effect of maternal burden of infection such as bacterial infection of the genitourinary tract and bacterial vaginosis. Other than local infection of the genitourinary tract, potential infections distant from the placental complex or the genitourinary tract, due to an indirect action of translocated bacterial products such as LPS and/or the action of maternally induced inflammatory mediators may adversely affect pregnancy outcomes. Therefore, periodontal disease might be a newly considered risk factor of adverse pregnancy outcomes.

Periodontal pathogens, being gram-negative anaerobic bacterial species, may cause inflammation of the placental membrane. Bacterial LPS triggers release of a variety of biologically active mediators (eg IL-1β, TNF-α, and PGE₂), which may contribute to premature labour. Periodontal infections may also impair foetal growth and trigger increased levels of biological fluids that induce preterm labour. Case control studies showed that preterm deliveries were 7.5-fold more common in women with severe periodontal disease than in those with good periodontal health. Women whose periodontal condition worsens during pregnancy have an even higher risk of having a preterm baby. It has recently been reported in Medical News and Perspectives, published by the American Medical Association, that “now we need to tell women that, if possible, they should have a periodontal examination before they get pregnant or at least as soon thereafter as possible, so that they can be treated and perhaps reduce the chance of a premature birth”.

Periodontal disease and pulmonary infections

It is known that one of the most common routes of infection for bacterial pneumonia is aspiration of oropharyngeal contents. Oral bacteria have been implicated in the pathogenesis of this disease and, in this regard, dental plaque might be an important reservoir for these potential pathogens. It has been shown that bacteria that grow in the mouth and throat can be aspirated into the lower respiratory tract and lungs to contribute to respiratory diseases such as pneumonia or worsening lung conditions. A recent epidemiological study showed that people with poor oral hygiene were 4.5-fold more likely to have chronic respiratory disease than those with satisfactory oral hygiene. A 25-year longitudinal study showed that alveolar bone loss due to periodontal diseases at baseline was an independent predictor of chronic obstructive pulmonary disease incidence. However, there is no strong evidence that periodontal diseases directly cause chronic obstructive pulmonary disease. Rather, periodontal disease may be an indicator of risk for lung disease, and these two disease conditions may share a common host susceptibility factor related to an underlying inflammatory response trait.

Dentist and doctor collaboration for better health

Dentistry and medicine have, to a great extent, been somewhat separate during the past 160 years, despite the fact that they have the same patients in common. The current theories of periodontal infections and systemic health interactions represent a new and crucial area for research that has far-reaching clinical implications. As the systemic disorders discussed in this article (CVD, diabetes mellitus, adverse pregnancy outcomes, and pulmonary infections) are all affected by many factors, it is difficult to determine the significance of periodontal diseases in the pathogenesis of these diseases. More well-controlled intervention studies are warranted to confirm that periodontal infections could be true risk factors for these important systemic diseases and that the management of relevant medical conditions could be improved by periodontal treatment and regular maintenance care. It is known that some risk factors are shared for periodontal disease and certain systemic diseases such as CVD. It is essential that the dentists know more about systemic diseases, and that the medical doctors know about oral diseases and their associations with the systemic disorders discussed above.

The advent of so-called periodontal medicine will promote a strong collaboration of dental professionals and medical professionals for better diagnosis and treatment across specialities. With medical doctors and dentists working closely together, more patients with systemic diseases are likely to be successfully treated, and patients will benefit from predictable treatment regimens to save and rehabilitate their dentition. The promotion of health and management of disease should require interdisciplinary education, updated knowledge and treatment strategies, and state-of-the-art health care delivery. While recognising and upholding the separateness of the dental and medical professions and sustaining and expanding the body of knowledge and practice that has developed since the foundation of dentistry as a separate profession from medicine, further integration of dental and general medicine requires a better communication between dentists and medical doctors, and more responsibilities and effective team approaches in the clinical management of their shared patients for better oral health and general health.

Suggestions for the treatment of patients with systemic diseases or conditions

Cardiovascular diseases

Patients with CVD and those known to be at risk for CVD, from family history or from examination, for example, hypercholesterolaemia, should be advised to have a comprehensive periodontal examination and to undergo appropriate periodontal treatment as indicated on the basis of dental history and the findings of a periodontal examination. The importance of long-term control of periodontal diseases should be part of comprehensive health education for such patients.
**Diabetes mellitus**

Patients with diabetes, especially those for whom control of the disease proves to be difficult and those at risk of developing the disease, should be advised to have a comprehensive periodontal examination and to undergo appropriate periodontal treatment as indicated. Physicians should recognise periodontitis as a complication of diabetes mellitus and as a condition that, if left unresolved, can complicate the management of diabetes mellitus. From a dental point of view, patients with diabetes mellitus should have a functioning dentition maintained or receive adequate oral rehabilitation for good function.

**Pregnancy**

Expectant mothers should be advised to have a comprehensive periodontal examination prior to pregnancy or as soon thereafter as possible and preventive periodontal care should be instituted to prevent pregnancy gingivitis. Appropriate periodontal treatment at a suitable stage of pregnancy should be delivered to pregnant women with active periodontitis to help reduce the risks of adverse pregnancy outcomes.

**Pulmonary diseases**

Patients with chronic obstructive pulmonary diseases and those at risk of developing such diseases should be advised to have a comprehensive periodontal examination and to undergo appropriate periodontal treatment as indicated.
