Clinical manifestations and outcomes of COVID-19 in the paediatric population: a systematic review

Maha Jahangir *, Marrium Nawaz, Deedar Nanjiani, Mishal S Siddiqui

Abstract

Objective: Coronavirus disease 2019 (COVID-19), the respiratory illness caused by severe acute respiratory syndrome coronavirus 2, has affected hundreds of thousands of people. We aim to report the distribution of cases, prevalence, and clinical, radiological, and laboratory signs and outcomes of COVID-19 in paediatric patients. Moreover, we intend to evaluate neonatal clinical outcomes. Hence, our age range of interest is 0 to 19 years.

Methods: A systematic literature review was conducted using the Medline database to identify papers published between 1 December 2019 and 9 April 2020 on COVID-19.

Results: The search identified 27 relevant scientific papers and letters. The review showed that the prevalence of COVID-19 in the paediatric population accounts for a small percentage of patients, whose clinical signs and symptoms are often milder than those of adults. Despite better prognosis and low mortality in children, the disease can progress to severe pneumonia in some cases, especially in the presence of co-morbidities. Children are likely to become a hidden source of infection because of their atypical presentation, and they may play a role in community transmission, leading to unfavourable outcomes. There is little evidence about intrauterine vertical transmission. As no vaccine or specific antiviral is currently available, management plans include supportive treatment.

Conclusion: As compared with that in adults, the presentation of COVID-19 in children is mild and has a better prognosis. Sufficient evidence regarding the probability of intrauterine vertical transmission could not be found, and further studies need to be conducted to establish this relationship.

Introduction

Severe acute respiratory system coronavirus-2 (SARS-CoV-2) outbreak emerged as a series of idioopathic cases of severe pneumonia in early December 2019, with the first report made to the regional office of the World Health Organization on 30 December 2019. The epidemiological curve of affected individuals rose steeply worldwide, thus leading to the outbreak being declared as a public health emergency of international concern on 30 January 2020 and subsequently a pandemic on 11 March 2020. As of 30 April 2020, 3090445 cases have been reported worldwide, with a mortality rate of 3.4%, culminating in the deaths of 217769 individuals.

Like other members of the Coronaviridae family, SARS-CoV-2, which causes coronavirus disease 2019 (COVID-19), is a positive-sense single-stranded RNA virus with an icosahedral capsid that primarily affects the respiratory tract. Other members of the family have caused pandemics with similar clinical presentations, such as Middle East respiratory syndrome–related coronavirus (MERS-CoV) and SARS-CoV. However, COVID-19 outnumbers both of the others in terms of cases and deaths, despite its lower mortality rate compared with SARS-CoV and MERS-CoV.

The COVID-19 outbreak primarily affects adults, and the severity of disease increases in an age-dependent fashion. Additional risk factors include male sex and co-morbidities including diabetes, hypertension, and previous respiratory impairments. Children and adolescents comprise a relatively minor proportion of patients who have tested positive for the virus. Moreover, the paediatric body responds to the disease differently from the adult body. This leads to heterogeneous clinical presentation, disease severity, and mortality rates across the age spectrum.

A review of 72314 cases by the Chinese Centre for Disease Control and Prevention reported that the age-groups of 10 to 19 years and under 10 years contributed 1% each to the total disease burden. Children aged under 18 years have been reported to...
兒科人群的2019冠狀病毒病臨床表現和療效：
系統綜述
Maha Jahangir, Marium Nawaz, Deedar Nanjiani, Mishal S Siddiqui

目的：2019冠狀病毒病（COVID-19）是由嚴重急性呼吸綜合症冠狀病毒2型引起的呼吸系統疾病，已影響達數十萬人。本文旨在報告兒科患者的COVID-19病例分佈、現患率，以及臨床、放射學和實驗室體徵及療效，並試圖評估新生兒的臨床療效。因此，我們的研究年齡範圍介乎0至19歲。

方法：使用Medline數據庫進行系統性文獻綜述，以識別2019年12月1日至2020年4月9日期間發表的COVID-19文獻。

結果：經搜索識別27篇相關科學論文和信函。本文說明COVID-19在兒科人群中的現患率頗低，其臨床症狀和體徵通常較成人轻微。儘管兒童的預後較佳且死亡率較低，但在某些情況，尤其出現併發症的情況下，COVID-19可能惡化至嚴重肺炎。由其非典型表現，兒童可能成為隱性感染源，在社區傳播後可導致不良結果。有關宮內垂直傳播的證據很少。由於目前尚無疫苗或特抗病毒藥物，因此支持治療屬管理計劃的一環。

結論：與成人相比，兒童於COVID-19的表現較輕微和預後較佳。找不到有關宮內垂直傳播可能性的充分證據，須作進一步研究。

Results and Discussion
The clinical manifestations and outcomes of COVID-19 in the paediatric population are summarised in Table 1.10,11,14-16,18-30,33,39-41

Age
Korean data suggested that a 10-year-old female child was the first paediatric case, and the youngest paediatric case of COVID-19 as of 2 March 2020 was a 45-day-old male baby.42 To date, the youngest reported paediatric case was a 36-hour-old baby in China.13

The median age of the paediatric patients with COVID-19 from Madrid, Spain was 1 year (range, 0-15 years). The largest dataset of 2143 paediatric patients from China reported the median age at diagnosis as 7 years.14 However, in the largest-to-date American dataset of 2572 COVID-19 cases in children aged <18 years, the median age was reported as 11 years.10

Comparing the two large studies,10,14 we believe that there is variation in the median age between different regions of the world. However, paediatric data from other parts of the world to confirm this are still lacking. We deduce that children of all ages can be infected, including neonates, infants, and young children.

Sex

An observational cohort study of 36 patients identified that 64% of the patients infected with SARS-CoV-2 were male. This is consistent with findings from other small studies. However, a large study by Dong et al did not find any statistically significant trend in the sex of paediatric patients, with boys comprising 1213 cases (56.6%). This is in line with another large study from the US describing 2490 paediatric cases: 57% of the patients were male.

Incubation period

The incubation period of COVID-19 ranged from less than 1 day to as long as 16 days. The median incubation period in children reported by Han et al and Shen et al was 5 days and 7.5 days, respectively.

Symptoms

Infected children were either asymptomatic or reported symptoms like fever and dry cough as the most common symptoms. Data reported by the US Centers for Disease Control and Prevention resonate with these findings: fever and cough were reported in 56% and 54% of the paediatric patients, respectively, whereas in another study, 68% of the paediatric cases had no obvious symptoms. A case series comprising of six patients reported fever and cough in all of them and vomiting in four of them. These results were confirmed by Xia et al, who found cough almost equally frequently as fever (65% and 60%, respectively). However, polynoepa has been reported as the most common symptom in severely affected patients, followed by fever and cough. A high proportion of patients presented initially with gastrointestinal symptoms such as nausea, vomiting, abdominal pain, constipation, and diarrhoea. Other reported symptoms were fatigue, myalgia, headache, and upper respiratory tract symptoms such as sore throat, nasal discharge, tachycardia, and expectoration. Presentation of COVID-19 in paediatric patients is much milder than that in adults. Therefore, children may be a hidden source of infection. Fever, cough, and shortness of breath were more commonly reported among adult patients (93%) than paediatric patients (73%). Another study showed a statistically significant difference between symptomatic presentation in children and adults (P<0.0001): fever (36% and 86%, respectively), cough (19% and 62%), pneumonia (53% and 95%), and severe disease type (0% and 23%). In contrast, gastrointestinal symptoms were more common in children. Another difference was observed between the median duration of fever in children (1 day; range, 0-3 days) and adults (4 days; range, 1-10 days).

### Figures

1. **Incubation period**: The incubation period of COVID-19 ranged from less than 1 day to as long as 16 days. The median incubation period in children reported by Han et al and Shen et al was 5 days and 7.5 days, respectively.

2. **Symptoms**: Infected children were either asymptomatic or reported symptoms like fever and dry cough as the most common symptoms. Data reported by the US Centers for Disease Control and Prevention resonate with these findings: fever and cough were reported in 56% and 54% of the paediatric patients, respectively, whereas in another study, 68% of the paediatric cases had no obvious symptoms. A case series comprising of six patients reported fever and cough in all of them and vomiting in four of them. These results were confirmed by Xia et al, who found cough almost equally frequently as fever (65% and 60%, respectively). However, polynoepa has been reported as the most common symptom in severely affected patients, followed by fever and cough. A high proportion of patients presented initially with gastrointestinal symptoms such as nausea, vomiting, abdominal pain, constipation, and diarrhoea. Other reported symptoms were fatigue, myalgia, headache, and upper respiratory tract symptoms such as sore throat, nasal discharge, tachycardia, and expectoration. Presentation of COVID-19 in paediatric patients is much milder than that in adults. Therefore, children may be a hidden source of infection. Fever, cough, and shortness of breath were more commonly reported among adult patients (93%) than paediatric patients (73%). Another study showed a statistically significant difference between symptomatic presentation in children and adults (P<0.0001): fever (36% and 86%, respectively), cough (19% and 62%), pneumonia (53% and 95%), and severe disease type (0% and 23%). In contrast, gastrointestinal symptoms were more common in children. Another difference was observed between the median duration of fever in children (1 day; range, 0-3 days) and adults (4 days; range, 1-10 days).
Dong et al.14 reported that only 34.1% of cases were laboratory-confirmed, whereas the remainder had clinically suspected disease on the basis of their symptoms. However, this does not rule out their chance of other respiratory infections, so we cannot fully rely on clinical suspicion. Children with SARS-CoV, SARS-CoV-2, and H1N1 influenza presented with somewhat similar symptoms, with the most common being fever. However, cough and pharyngeal congestion are not as common in SARS-CoV-2 (7% and 3%, respectively) as in SARS-CoV (64% and 14%) and H1N1 influenza (83% and 95%). These findings indicate that SARS-CoV-2 has little effect on the upper respiratory tract of children.15,24,25

There are many plausible explanations for why the disease’s manifestations are milder in the paediatric population as compared with adults. First, it is very rare for children to have co-morbidities like diabetes, cardiovascular disease, and hypertension. Adults have a higher prevalence of C-reactive protein and longer duration of fever, suggesting a stronger immunological response compared with that in children.15,18 Further, children tend to remain at home and have fewer opportunities for exposure to pathogens or patients. Angiotensin-converting enzyme II is the receptor speculated to be affected by SARS-CoV-2.43,44 Children are less sensitive to COVID-19 because of their lower maturity and binding ability to a different distribution of angiotensin-converting enzyme II receptors.45 Furthermore, children experience respiratory infections in winter more often than adults do, which may result in higher levels of antibodies against other respiratory viruses, providing cross-protection against SARS-CoV-2. Additionally, children are mostly infected by the second or third generation of viral infections; hence, the viruses with which they are infected have weak virulence. Further, children’s immune response is still under development and may show different responses to pathogens than that of adults.23,24 A different yet possible explanation is that like SARS and MERS-CoV infection in children, SARS-CoV-2 infection may follow a much milder and shorter course.21

**Radiological findings**

Among the studies that focused on radiographic findings in paediatric patients (n=224), 147 (65.6%) patients showed positive findings suggestive of pneumonia. Most of the patients presented with abnormalities, such as multiple bilateral, peripheral ground-glass opacities (GGO), and consolidation.15,18-20,23,24,27,29 In comparison with adults, pulmonary inflammatory changes have been reported to be milder,15,23,24 and nodular changes (75%), revealed as halo sign and air bronchogram sign on computed tomography (CT), are more common in paediatric patients.16,22,23 Therefore, these should be considered as typical signs in paediatric patients.

Chest CT images demonstrated bilateral lung involvement in about 70% of children aged <3 years, and unilateral lesions and normal lungs were reported more frequently in children aged ≥6 years.21 Lesions were mainly distributed in the middle and outer bands of the lungs near the pleura. However, 53% had no obvious abnormalities.22 When another group of 24 asymptomatic carriers was reviewed, 29.2% had normal CT images.30 Feng et al.19 examined nine of the 15 confirmed paediatric patients, of whom 54% had no clear symptoms on admission. However, their CT results were typical of SARS-CoV-2 infection. Chest CT scans revealed improvement in children after 3 to 5 days of treatment.17,20,24,29 However, lesions were sometimes still visible on chest CT despite two consecutive negative nucleic acid tests.16

The severity of the lesions was limited in the early stage, but they increased in density as the disease advanced, involving multiple lobes bilaterally.16,22 Earlier in the course of disease, CT showed consolidation with surrounding halo sign, GGO, fine mesh shadow, and tiny nodules in 50%, 60%, 20%, and 15% of cases, respectively.16 In severely
ill patients, bilateral multiple patch-like shadows, GGO, ‘white lung’ change accompanied by air bronchogram sign, and pleural thickening was the characteristic picture on CT. In neonates, chest X-ray commonly showed GGO and blurred lung margins followed by bilateral pneumothorax and signs of neonatal respiratory distress syndrome. Computed tomography features could play an important role in screening suspected cases radiographically while awaiting confirmation by real-time reverse transcription–polymerase chain reaction (PCR), the results of which could be used to decide the subsequent plan of action. Computed tomography can also be useful in cases that yield multiple false-negative real-time reverse transcription–PCR tests despite being clinically symptomatic.

Laboratory findings

Analysis of laboratory tests has revealed different laboratory parameters in children compared with adults. In children, the peripheral white blood cell count and absolute lymphocyte count are usually normal or slightly reduced. In contrast, laboratory analyses of adults have shown low leukocyte counts and significant reductions in absolute peripheral blood lymphocyte counts. One study revealed leukopenia as a common finding among adults (20%), whereas leukocytosis was more frequent in children (28.6%); P = 0.014. One study found an elevated lymphocyte count on the initial routine blood test in 66% of paediatric subjects. Although the association is not clear, this altered immune response and lack of significant lymphopenia might help to cause the milder presentation in children. Some features differed significantly according to disease severity. Sun et al observed normal or mildly raised levels of leukocytes, neutrophils, and lymphocytes in severely ill patients, whereas low counts were observed in critically ill patients with serious complications. Abnormalities in the cytokine spectrum, characterised by increased plasma concentrations of inflammatory cytokines, were seen more frequently in critically ill than severe patients.

Inflammatory markers like C-reactive protein and erythrocyte sedimentation rate were normal or transiently elevated. Raised levels of procalcitonin (PCT) were linked with severe disease in children. The erythrocyte sedimentation rate was raised significantly in adults as compared with children (P = 0.047), whereas PCT was elevated in 42.9% of children but no adult patients (P = 0.007). Elevated PCT in children may indicate bacterial co-infection, and timely administration of antibiotics might prove beneficial.

Another characteristic feature of COVID-19 is that it affects vital organs like the lungs, liver, and heart, indicated by increased levels of myocardial enzymes, aspartate aminotransferase, alanine aminotransferase, and D-dimer. Myocardial zymography revealed a higher frequency of elevated levels of isoenzyme in children than in adults. The level of creatine kinase, an indicator of myocardial injury, is significantly higher in severely ill patients. Moreover, brain natriuretic peptide has been found in a few paediatric patients. The presence of creatine kinase and brain natriuretic peptide indicates that SARS-CoV-2 has the potential to cause heart injury. Therefore, attention should be paid to those laboratory results.

In summary, the laboratory findings reported in children with SARS-CoV-2 are inconsistent with those observed in adult cases. Disease progression is characterised by amplified inflammatory response or cytokine storm. Monitoring of laboratory parameters is suggested to identify patients who might show improvement with anti-inflammatory treatments.

Treatment

The principles of early identification, early isolation, early diagnosis, and early treatment should be stressed. Our review did not identify any treatment protocols or trials specific to the paediatric population. Although most children with mild disease may not have indications for hospitalisation, supervision must be ensured to contain and prevent transmission. As no vaccine is currently available, management plans include bed rest and supportive treatments like maintenance of water electrolyte balance and homeostasis, administration of antipyretics, and administration of broad-spectrum antibiotics because of the probability of co-infections.

Given by spray or nebulisation in the early phase of disease, interferons, alone or in combination with other antivirals, have been shown to improve symptoms. Oral lopinavir/ritonavir or ribavirin have been used; however, their efficacy and safety remain to be determined. Corticosteroids and intravenous immunoglobulin have been used in severe cases only. Use of steroids for treatment of SARS-CoV and MERS-CoV resulted in increased rates of secondary bacterial and fungal infections and longer duration of hospital stay. Thus, in addition to suppressing the inflammatory response, steroids also delay viral clearance. Because of the lack of evidence regarding efficacy, the World Health Organization’s interim guidance advised against the use of steroids for treatment of novel coronavirus, unless indicated. For such cases, it is recommended to use steroids only in the short term, and only as a part of a clinical trial, to efficiently weigh their harms and benefits. Patients with COVID-19 should be closely
monitored for signs of clinical deterioration, such as rapidly progressive respiratory failure, central cyanosis, coma, convulsion, and sepsis. If respiratory distress develops despite the use of a naso-catheter or mask oxygenation, a heated humidified high-flow nasal cannula and non-invasive ventilation should be used to target $\text{SpO}_2 \geq 94\%$. Mechanical ventilation with endotracheal intubation should be adopted when no improvement is seen. Increased levels of pro-inflammatory factors have been seen in children. Zheng et al reported two patients with congenital heart disease, one of whom also had malnutrition and metabolic diseases. Among 345 paediatric cases with information on underlying conditions, 23% had at least one underlying condition, with chronic lung disease being the most common, followed by cardiovascular and immunosuppressive diseases. Tagarro et al reported that 27% of patients had underlying disease. Furthermore, Xia et al reported that 35% patients had a history of underlying diseases, which may indicate that such patients are more susceptible to SARS-CoV-2.

Outcomes

Although paediatric patients are susceptible to COVID-19, the case fatality rate of severe paediatric patients is much lower than that of adults (49.0%), which indicates that they have favourable outcomes compared with adults. Paediatric patients mostly recover in 1 to 3 weeks and are generally discharged after consecutive negative nucleic acid tests. Tagarro et al reported that 60% of paediatric patients were hospitalised, with only 10% admitted to paediatric intensive unit care. Sun et al also reported that most severely ill patients recovered and were discharged. Another two children who received paediatric intensive unit care recovered without any adverse outcomes reported.

Disease duration is relative to the severity of the disease: the duration is over 10 days across all patients and over 20 days in critically ill patients. Qiu et al concluded that patients with the moderate clinical type spent more days in hospital compared with those with mild clinical type ($P=0.017$). The length of hospital stay has varied between different studies: the minimum and maximum averages reported have been 8.3 and 15.3 days, respectively. Because this parameter is multifactorial and influenced by isolation policy and the availability of health facilities and laboratory tests in different hospitals, the length of hospital stay does not necessarily predict the prognosis, and detailed analysis is expected on its significance.

Overall, the prognosis in neonates is also good. Most of them have been discharged after consecutive negative nucleic acid test results. A few have been kept under observation despite stable condition and negative clinical and radiological findings because of positive COVID-19 pharyngeal swab nucleic acid test results.

Complications

Almost all studies have reported recovery without any complications. In critically ill patients, septic shock and multiple organ dysfunction syndrome were the most common complications, and intussusception, toxic encephalopathy, status epilepticus, disseminated intravascular coagulation (DIC), hydrenephrosis, cardiac insufficiency, coagulopathy, hypoglycaemia, and gastroenteritis were also reported. One study reported two critical cases with abnormal renal function and coagulopathy.

Deaths

In China, the deaths of a 14-year-old boy and a 10-month-old baby with intussusception who developed multi-organ failure 4 weeks post-admission were reported. Three paediatric deaths were reported in the US. None had been reported in Italy or Spain as of 15 March and 8 April 2020, respectively.

Window of stool polymerase chain reaction detection

The ability of SARS-CoV-2 to infect the gastrointestinal tract is supported by detection of its nucleic acids in stool samples from adults and children. In spite of negative nucleic acid results from throat swab specimens, children's stools were still nucleic acid–positive after 10 days of recovery. Other studies have reported re-admission of discharged children with positive stool specimens but negative respiratory specimens. Although their prognosis is better than that of adults; the period of PCR positivity is longer in children. Poorer hand hygiene practices causing faecal-oral transmission might be a reason for the delayed clearance of viral RNA in children's stools. Although positive results cannot confirm that live virus is present in the stool, this still increases the infection risk to the public, so follow-up of specimen collection should be considered. The isolation period for children should be reviewed because of the transmission risk.
Transmission patterns

The virus is mainly transmitted through respiratory droplets or contact. Transmission among the paediatric population mostly occurs by close contact with family members, according to Wang et al. 90% of cases were clustered in families. Another study reported that 62.5% of cases were associated with familial clustering. Neonates and infants are more likely than adults to be infected via close contact with COVID-19-positive family members.

Potential of intrauterine vertical transmission

To date, nine studies have reported on neonates born to COVID-19 positive mothers (n=115); only seven of those neonates were SARS-CoV-2-positive. Xia et al, Yu et al, and Zeng et al reported that 3/20 (15%), 1/7 (14%), and 3/33 (9%) neonates were positive, respectively. Despite the placenta and cord blood being negative for SARS-CoV-2, one neonate was diagnosed as positive 36 hours after birth. Other studies have also found that the placenta, cord blood, and breast milk were negative for SARS-CoV-2. Because of the limited evidence regarding vertical transmission, we speculate that close contact could explain the positive results. We are still not confident about the probability of vertical maternal-fetal transmission, and further studies need to be performed on this subject. Neonates born to infected mothers should be separated immediately after birth and undergo an isolation period.

Impact of COVID-19 on fetal outcomes

Although the majority of the studies showed that neonates were negative for SARS-COV-2 and that

most neonates had excellent outcomes, a few studies revealed that neonates born to COVID-19-positive mothers could develop other complications that could lead to poor neonatal outcomes. The rate of premature birth among newborns born to mothers with confirmed COVID-19 pneumonia (23.5%) was significantly higher than the 2020 and 2019 control rates (5.8% and 5.0%, respectively). Low birth weight was also more frequent in infants of infected mothers (17.6%) than in the control group (2.5%). Some incidence of premature birth, fetal distress, premature rupture of membranes, small size for gestational age, and large size for gestational age was observed in neonates born to COVID-19-positive mothers. Two COVID-19-positive neonates developed DIC, of whom one died on the 9th day secondary to refractory COVID-19, leading to unfavourable outcomes and causing community transmission. The probability of intrauterine vertical transmission in neonates is low, and close contact is the only plausible explanation for the observed positive results in neonates.

Author contributions
M Jahangir designed the study. All authors contributed to the acquisition and analysis of data, and wrote the manuscript. M Jahangir had critical revision of the manuscript for important intellectual content. All authors had full access to the data, contributed to the study, approved the final version for publication, and take responsibility for its accuracy and integrity.

Conflicts of interest
The authors have disclosed no conflicts of interest.

Funding/support
This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.
